Abstract— Network Security has become the key foundation with the tremendous increase in usage of network-based services and information sharing on networks. Intrusion poses a serious risk to the network security and compromise integrity, confidentiality & availability of the computer and network resources. Intrusion Detection System (IDS) is one of the looms to detect attacks and anomalies in the network. Data mining technique has been widely applied in the network intrusion detection system by extracting useful knowledge from large number of network data. In this paper a hybrid model is proposed to maximize the effectiveness in identifying attacks that integrates Anomaly based Intrusion detection technique with Signature based Intrusion detection technique is divided into two stages. In first stage, the network traffic anomaly detection (NETAD) which is anomaly based IDS is combined with the signature based IDS SNORT which is an open-source project. In second stage, Entropy for network features is used for feature reduction and data mining techniques “k-means + CART”, to cascade k-means clustering and CART (Classification and Regression Trees) for classifying normal and abnormal activities. The hybrid IDS model is evaluated using KDD Cup Dataset.

Key words: Anomaly Detection, Intrusion detection, data mining, k-means, CART, NETAD, SNORT

I. INTRODUCTION

In recent years, with the tremendous growth in networked computer resources, a variety of network-based applications have been developed to provide services in different areas such as ecommerce services, social media services, banking services, government services, etc. The increase in the number of networked machines has lead to an increase in unauthorized activity, not only from external attacks, but also from internal attacks, such as people gaining unprivileged access for personal gain [4]. Intrusion detection system (IDS) detects unauthorized intrusions into computer systems and networks. Incidents may be malware attacks (such as worms, virus), attackers gaining unauthorized access to system through Internet or user of the system gaining unprivileged root access of the system for which they are not authorized. An IDS monitors network traffic of a computer system like a network sniffer and collects network log data. The collected network data is analyzed by intrusion detection model or technique for rule violations. When any rule violation is detected the IDS alerts the network administrator by raising alarm. Fig. 1.1 illustrates the overall architecture of Intrusion detection system.

A. IDS Detection Methods:

1) Signature-Based Detection:
Signature-based detection is the process of comparing signatures/patterns of known attack with the observed events to identify possible incidents. The most common form of signature based IDS used commercially specifies each pattern of events that corresponds to an attack as a separate signature.

a) Advantages:
Signature based detectors are very effective in detecting known attacks or threats that are predefined in the database of IDS.

b) Disadvantages:
Signature based IDS are unable to detect unknown attacks or variants of known attacks. Database of signature based IDS has to be manually revised for each new type of attack that is discovered.

B. SNORT:
Snort is an open source IDS. It is a signature based technique because it detects the attack based on the set of rules that are predefined within the Snort. If any attack data is found then it automatically drops the packet otherwise the particular record is considered as a normal data. Snort is rule based technique that defines new rules.

Snort consists of the following four components [2]:

1) Packet capture/decode engine: It uses the libpcap packet-capturing library written in Lawrence Berkeley National Laboratories. Captured packets are then processed by decoding engine and decoded packets.

2) Preprocessor plug-ins: Packets are passed through a number of preprocessors for investigation and process packets before they are passed to detection engine.

3) Detection engine: It tests the data packets for a number of attributes stated in Snort rules definition file.

4) Output plug-ins: It accept alarms generated from preprocessors, detection engine, or decoding engine.

1) Anomaly-Based Detection:
Anomaly-Based detection compares definitions of what activity is considered normal against observed events to identify significant deviations [16]. Anomaly based IDS uses profiles that represent the normal behaviour of system, applications or network traffic that are developed by
analyzing the characteristics of typical activity over period of time [16].

a) **Advantages:**
Anomaly based IDS are able to detect new or unknown attacks or abnormal behaviour. Anomaly detection has the advantage that no rules need to be written and it can detect novel or new attacks.

b) **Disadvantages:**
Profiles can sometimes be inaccurate which results into generation of false alarms considering normal data as an attack. Profiles should be updated constantly.

C. **NETAD:**
Network traffic anomaly detector (NETAD) is the anomaly-based approach. NETAD models protocols rather than the user behaviour because the majority of the attacks exploit protocol implementation bugs and can only be understood by detecting unusual input and output. It uses a time-based model which assumes a quick change in a short time in the network statistics. NETAD operates in two phases: first phase is the filtering of incoming client sessions to distinguish beginning of sessions and second phase are the modeling phase. The filtering phase eliminates the traffic up to 98-99%. Only the traffic data, which evidence of attacks are included in is passed to the modeling phase. The second phase models nine types of packets. Thus total 9 * 48 = 432 rules are available. Nine mostly used protocols are as follows [2]: All IP packets, All TCP packets (if protocol = TCP), TCP SYN (if TCP and flags = SYN), TCP data (if TCP and flags = ACK), TCP data for port numbers between 0 and 255 (if TCP and ACK and DP1 = (high order bit of destination port) = 0), Telnet (if TCP and ACK and DP1 = 0 and DP0 = 21), FTP (if TCP and ACK and DP1 = 0 and DP0 = 23), SMTP (if TCP and ACK and DP1 = 0 and DP0 = 25), HTTP (if TCP and ACK and DP1 = 0 and DP0 = 80).

1) **Data Mining In Intrusion Detection System:**
Data Mining refers to the process of extracting effective, updated, latent, useful, and the understandable pattern from a large incomplete, noise, non-stable and random data. In intrusion detection system, the information deals from multiple sources such as network traffic or logs, system logs, application logs, alarm messages, etc. Due to varied data source and format, the complexity increased in auditing and analysis of data. Data Mining has huge advantage in data extraction from large volumes of data that are noisy and dynamic, thus it is of great importance in intrusion detection system.

a) **K-Means:**
K-means is a partitioning method in clustering technique of data mining. K-Means clustering method is used to partition the training data into k clusters with the help of Euclidean distance similarity [4]. It is an algorithm to group or to classify the objects based on attributes/features into k number of clusters. Euclidean Distance equation to find distance between two objects is:

\[ D(a,b) = D(h,a) = |a-b| = \sqrt{\sum_{i=1}^{n}(b_i - a_i)^2} \]

Basic steps for clustering the data by k-means are:

- Select a number (k) of cluster centers - centroids (random)
- Assign every object to its nearest cluster center (e.g. using Euclidean distance)
- Move each cluster center to the mean of its assigned objects
- Repeat steps 2,3 until convergence (change in cluster assignments less than a threshold)
- Advantage:
  - Relatively efficient in grouping normal or abnormal data.
  - Disadvantage:
    - Unable to handle noisy data.

b) **CART (Classification and Regression Trees):**
Classification tree analysis is used to identify the “class” to which the data belongs. Regression tree analysis is where the data is continuous and tree is used to predict its value. The term Classification and Regression Tree (CART) analysis is used to refer to both of the above procedures. Classification and regression trees are machine-learning methods for constructing prediction models from data. The Classification and Regression Trees (CART) methodology is technically called as binary recursive partitioning [21]. The process is binary because parent nodes are always split into exactly two child nodes and recursive because the process is repeated by treating each child node as a parent. The key elements of CART analysis are a set of rules for splitting each node in a tree; deciding when tree is complete and assigning a class outcome to each terminal node.

The main steps of CART are:
1) Rules for splitting data at a node based on value of a variable
2) Stopping when a branch becomes a leaf/terminal node and cannot be split further
3) Finally a prediction for target variable in each leaf/terminal node.

2) **Advantages:**
- CART does not rely on data belonging to a particular type of distribution.
- It is not significantly impacted by outliers in input data.

3) **Feature Reduction:**
The noisy or irrelevant data results into lengthy intrusion detection process. It also degrades the performance of intrusion detection system. Feature reduction technique can be applied to obtain reduced representation of data set that is much smaller in volume and yet maintains the integrity of the original data [11].

a) **Entropy-Based Feature Reduction:**
Entropy is the measurement of uncertainty or randomness [3]. Entropy of different network features are calculated to create anomaly based intrusion detection system. If the entropy of network features deviate from a predefined range that indicates the randomness or abnormality in the network traffic that is anomaly in the network traffic. The value of network entropy tends towards 1 when there is high level of uncertainty in the traffic.

Entropy for the variable: 

\[ H_i = - p_i \log p_i, \text{ where } p_i = \text{probability of that variable} \]
II. LITERATURE REVIEW

A. EDADT Algorithm, SNORT + ALAD +LERAD \(^{[1]}\)

The EDADT algorithm is formed by using two algorithms Hybrid PSO + C4.5. The Hybrid IDS model is formed by using SNORT IDS and two pre-processors ALAD and LERAD. SNORT detects only profile based attacks and the anomaly based approaches such as Application Layer Anomaly Detector (ALAD) and Learning Rules for Anomaly Detection (LERAD) is used to perform better prediction. Semi-Supervised Approach, the labeled data can be labelled using the unlabeled data. The labeled training data are applied to the SVM classifier. In Varying HOPERA algorithm, a variable clock drift method is proposed to avoid the client waiting time for server and at the same time message loss is avoided greatly. The proposed algorithm has been tested using KDD Cup dataset. KDD Cup 99 data set contains 23 attack types. The framework of proposed methodology is shown in Fig. 2.1.

![Fig. 2.1: Framework of methodology in Intrusion Detection System \([1]\)](image)

The accuracy, sensitivity and specificity values for Improved EDADT algorithm are 98.12%, 96.86% and 92.36%. SNORT+ALAD+LERAD have detected 149 attacks out of 180 attacks. Semi-Supervised Approach shows 98.88% in terms of accuracy compared to the existing algorithms like Reduced Support Vector Machine, Semi-Supervised clustering algorithm (PCKCM) and Fuzzy Connectedness based Clustering also shows 0.5% false alarm rate respectively in compared to methods such as R SVM, one step Markov, order 10 Markov, Markov chain+ drift, PCKCM and FCC. The proposed varying HOPERA algorithm has been compared with the existing HOPERA using throughput and packet size metrics. With the help of varying clock drift, the message loss is greatly reduced and the client can easily communicate with the server with minimum contact initiation trails and the improved maximum delivery latency has been achieved.

B. SNORT+PHAD+NETAD \(^{[2]}\)

The hybrid IDS is obtained by combining (PHAD) packet header anomaly detection and (NETAD) network traffic anomaly detection which are anomaly-based IDSs with the misuse-based IDS.

1) SNORT:

Snort is a rule-based network intrusion detection system. Every rule consists of two logical parts: the rule header and rule options. The rule header has five sections; rule actions (the action to be taken when an intrusion is detected), the end-to-end source and destination information (source IP addresses, destination IP addresses and port numbers depending on the protocol), and protocol type (TCP, UDP, or ICMP). The rule options consist of different conditions that help deciding whether the mentioned misuse operation has occurred or not.

2) PHAD:

Packet header anomaly detector (PHAD) is the first anomaly based approach added to Snort as a preprocessor in this study. PHAD is different from other network-based anomaly detection systems by two reasons. Firstly, it models protocols rather than the user behavior because the majority of the attacks exploit protocol implementation bugs and can only be understood by detecting unusual input and output. Secondly, it uses a time-based model, assuming a quick change in a short time in the network statistics. PHAD reduces false alarm rate by flagging only the first anomaly as an alarm.

C. Network Traffic Anomaly Detector (NETAD):

Network traffic anomaly detector (NETAD) is second anomaly based approach added to Snort as a pre-processor in this study. The NETAD also models packets as PHAD. NETAD operates in two phases: First is the filtering of incoming client sessions to distinguish beginning of sessions. Second is the modeling phase. Filtering phase eliminates the traffic up to 98–99%. Elimination simplifies the traffic for the modeling phase. Thus only the traffic data which evidence of attacks are included in is passed to the modeling phase.

D. Combining PHAD and NETAD to Signature-Based IDS Snort:

Snort’s preprocessor architecture has been used to combine PHAD and NETAD with Snort. Snort has detected 27 attacks out of 201 attacks available in IDEVAL data. Snort + PHAD have detected 51 attacks and Snort + PHAD + NETAD detected 146 attacks. It is clear NETAD is added as a pre-processor Snort becomes a more powerful IDS.

III. ENTROPY BASED IDS, SVM BASED ANOMALY DETECTION \(^{[3]}\)

A. Entropy Based IDS:

The entropy of network features is the measurement of uncertainty or randomness which if deviates from a predefined range, indicates the randomness or abnormality in the network traffic that is anomaly in the network traffic. Value of network entropy tends towards 1 when there is high level of uncertainty in the traffic

B. SVM Based Anomaly Detection:
SVM model is the classification technique that models different network features for classifying the normal and attack traffic.

A hybrid technique which is a combination of both entropy of network features and support vector machine is compared to the individual methods. Normalized entropy of network features are calculated and sent to SVM model for learning the behaviour of the network which classifies the network traffic in normal or attack traffic. The DARPA Intrusion Detection Evaluation dataset is used to evaluate the methods.

The experimental results of Entropy based system are 85.71% correctly classified and 14.29% misclassified and that of SVM based system is 77.71% correctly classified and 22.29% misclassified. The results of hybrid technique are 97.25% correctly classified and 2.75% misclassified. In addition, hybrid approach yields more accuracy than entropy and SVM based techniques.

IV. K-MEANS CLUSTERING + C4.5 DECISION TREE METHOD

A. Anomaly Detection with K-Means Clustering:
The k-Means algorithm groups n data points into k disjoint clusters, where k is a predefined parameter. Steps in the k-Means clustering-based anomaly detection method are as follows:

1) Step 1: Select k random instances from the training data subset as the centroids of the clusters C1; C2; ...Ck.
2) Step 2: For each training instance X:
   - Compute the Euclidean distance D(Ci,X),i = 1,...k
   - Find cluster Cq that is closest to X.
   - Assign X to Cq. Update the centroid of Cq. (The centroid of a cluster is the arithmetic mean of the instances in the cluster.)
3) Step 3: Repeat Step 2 until the centroids of clusters C1; C2; ...Ck stabilize in terms of mean-squared error criterion.
4) Step 4: For each test instance Z:
   - Compute the Euclidean distance D(Ci,Z),i = 1,...k. Find cluster Cr that is closest to Z.
   - Classify Z as an anomaly or a normal instance using the Decision tree.

B. Anomaly Detection with C4.5 Decision Trees:
Given a set S of cases, C4.5 first grows an initial tree using the divide-and-conquer algorithm as follows:

1) If all the cases in S belong to the same class or S is small, then the tree is a leaf labeled with the most frequent class in S.
2) Else, choose a test based on a single attribute with two or more outcomes. Make this test the root of the tree with one branch for each outcome of the test, partition S into corresponding subsets S1, S2, S3,... according to the outcome for each case, and apply the same procedure recursively to each subset.

The performance of k-Means, ID3 decision tree, Naïve Bayes algorithm, K-Nearest Neighbors (K-NN), SVM algorithm, TCM–KNN (Transductive Confidence Machines for K-Nearest Neighbors) and the proposed cascading algorithm of K–Means and C4.5 algorithms is measured and the accuracy of the proposed (K–Means + C4.5) method is higher than other methods.

V. CART, BAYESIAN MODEL, ARTIFICIAL NEURAL NETWORK

In this paper we are using CART, Naïve Bayesian, and Artificial Neural Network Model data mining classification methods.

Classification and regression trees (CART) is a non-parametric technique that produces either classification or regression trees, depending on whether the dependent variable is categorical or numeric, respectively. An artificial neural network is a system based on the operation of biological neural networks, in other words, is an emulation of biological neural system. These methods have proved to be useful for gathering different knowledge for Intrusion Detection.

Classification and regression trees (CART) are a non-parametric technique that produces either classification or regression trees depending on whether the dependent variable is numeric or categorical respectively. Trees are formed by a collection of rules based on values of certain variables in the modeling data set. The rules are selected based on how well splits based on variables values can differentiate observations based on the dependent variable. Once a rule is selected and splits a node into two, the same logic is applied to each “child” node. It is a recursive procedure.

Splitting of node stops when CART detects no further gain can be made, or some pre-set stopping rules are met. Each branch of the tree ends in a terminal node. Each observation falls into one and exactly one terminal node. Each terminal node is uniquely defined by a set of rules. We used machine learning tool, Weka3.6 for analyzing the results. Weka3.6 does not support large databases; hence we have not used some of the attributes. The result shows that the performance of the Induction tree method and ANN methods are better than the NB classifier.
