Abstract— This paper reviews the different methods that could be used for CO2 separation from flue gases in IGCC power plant. The concentration of CO2 gases increases in atmosphere day by day. CO2 gases are responsible for greenhouse gas emissions which is the greatest environmental challenge in these days. Membrane separation, adsorption, carbon capture and storage (CCS) are some methods to separate CO2. Membrane separation include inorganic membrane, polymeric membrane, hollow fiber membrane and novel CO2 capture technology and these method is clean and easier method. Adsorption process helps to reduce CO2 gas emission by use of selective adsorbents. Carbon capture and storage (CCS) are another method involves collecting, transporting and then burying.

Key words: Membrane Gas Method, Carbon Capture and Storage (CSS), Adsorbents

I. INTRODUCTION

Many greenhouse gases present in our atmosphere. There are two ways by which greenhouse gases produce in our atmosphere i.e. First is naturally and second is industrially (i.e; flue gases from IGCC power plant etc). Some naturally gases are water vapour (H2O), carbon dioxide (CO2), methane (CH4), nitrous oxide (N2O) and other gases due to industrial process are Per fluorocarbons (CF4, C2F6), hydro fluorocarbons (CHF3, CF3CH2F, and CH3CHF2), and sulphur hexafluoride (SF6) are only present in the our atmosphere. CO2 emission is mainly responsible for greenhouse gas emission almost caused by burning of fossil fules. Water vapour is the most important, dominant and abundant greenhouse gas. Concentration of water vapour depends on temperature and other parameters [1-3].

Fig. 1: Global CO2 emission from flue gases [5]

The earth’s average temperature continuously increases day by day. Intergovernmental Panel on Climate Change (IPCC) say that Global GHG emissions must be reduced by 30 to 60 percent by 2050 to avoid dramatic consequences of global warming. [4].

II. MEMBRANE GAS METHOD FOR SEPARATION OF CO2 FROM FLUE GASES

A. Polymeric Membrane

By use of polymeric membrane method we can decrease the amount of CO2 from our atmosphere. Plasticization effects helps us to decrease the flux of CO2. By increasing the solubility of CO2 in polymeric membrane and by increasing the CO2 diffusion through membrane, we can achieve high performance of CO2 by this method. Solubility can be increased by change in polymer composition by using selective composition. CO2 diffusion can be increased by increasing free space volume. By insertion of bulk substitution groups we can increase free volume by annealing conditions and improve membrane casting methods[6]. Composite polymeric membranes are another method in polymeric membrane. These membranes consist of two segments i.e. glassy segment and rubbery segment. In which glassy segment is hard and rubbery segment is soft. Glassy segment helps to makes the structural backbone and rubbery segment helps to makes a thin film. Both the segments have high selectivity due to dense skin layer and high permeability. Mixture of polyimide has very high performance [6-9].

B. Inorganic Membranes

Inorganic membrane is second method to separate CO2, generally porous inorganic membrane are used. In porous inorganic membranes, a porous thin top layer is supported on a porous metal or ceramic support. Zeolite, glass, zirconia, titania, silicon carbide, carbon and alumina membranes are mainly used as porous inorganic membranes supported on different substrates, such as α-alumina, alumina, zirconia, zeolite, orporous stainless steel [10-13].

C. Hollow Fiber Membrane

Hollow fiber is the one which is most industrially important membranes for gas separations. For CO2 separation, Asymmetric Hollow fiber membranes are more favourable and absorption in gas-liquid membrane by low mass-transfer resistance and high permeability. High adsorption efficiencies can be achieved by this process due to much larger surface area required for gas liquid interface than conventional gas absorption processes [14-18].

Currently, membrane concept has addressed the limitations of membranes in various ways through fabrication of new type of mixed matrix membranes (MMMs) by incorporation of inorganic particles as fillers into polymer matrices. The performance of MMMs depends on textural properties of fillers, molecular sieving effect and membrane–penetrant interactions. The main challenges in the fabrication of MMMs is selection of fillers, which controls the gas separation characteristics of membranes. In this review, the
influences of fillers like zeolite, carbon, and metal organic framework in MMMs fabrication and their CO2 permeability and CO2/CH4 and CO2/N2 selectivity were compiled from recent reports.

Actually, the interest for commercial CO2 separation and capture can be strongly find by membrane technology, which has been evolved as a competitive technique in energy production and natural gas industries [21-23]. In all the separation technique pore diameter is very important for different separation technique so there may have the following figure such as:

![Cut-offs of pore diameter required for different separation techniques](image)

This figure shows the kinetic diameter of various gas molecules and pore diameter required for their separation. On the behalf of pore diameter gas separation method may be confined efficiently.

D. Mixed matrix membranes

Currently, membrane science consist the progress of Nano composite-based membrane for gas separation, which vanishes the task of individual polymeric. And inorganic membrane increases the separation performance. The low surface area, inadequate thermal stability, and chemical properties are the main challenges faced in the development of efficient commercial membranes. In addition to the above-mentioned membrane characteristics, mechanical properties such as crushing, abrasion, and attrition is also important in order to commercialize membrane Technology. Thus to lie on the same section some of these aim and to nullify the disadvantages of individual polymeric and inorganic membranes, MMMs or composite membranes are obtained by mixing the inorganic and polymeric phases, which may be linked via van der Waals forces and covalent or hydrogen bonds [43]. Therefore, selective literature has been compiled as a review on the composite membrane, especially focusing on the CO2 separation by MMMs.

III. CARBON CAPTURE AND STORAGE (CSS)

A. Pre-combustion capture

Pre combustion capture has a reaction of fuel with air and in some other cases a gas which is mainly composed of carbon monoxide and hydrogen is produced by steam, this produced gas are known as synthesis gas (syngas) or fuel gas. In catalytic reactor produced carbon monoxide is reacted with steam called shift converter, which give CO2 and more hydrogen gas. After this cryogenic distillation or chemical absorption process used to separate CO2, as a result hydrogen-rich fuel produced, which can be used in many applications such as gas turbines, engines, furnaces, and fuel cells [19-20].

B. Post-combustion capture

The higher CO2 concentration and pressure can be achieved in the output stream which is main advantage of post combustion chamber. The main disadvantage of pre-combustion capture is system needs long-term development in a number of enabling technical areas to achieve targeted efficiency towards a hydrogen economy. This disadvantage has limited application approach and it increased investment cost of pre-combustion capture [40-42].

C. Oxy-fuel combustion capture

Instead of ambient air nearly pure oxygen is used for combustion in oxy-fuel combustion and as a result, mainly CO2 and H2O are left in the flue gases, which are separated by condensing water. High flame temperature, high CO2 concentration in output stream and easy separation of exhaust gases are three major advantages of this method. The major disadvantages of oxy-fuel combustion are large electric power requirement to separate oxygen from air and high capital costs [23-25].

IV. ADSORBENTS

Carbonaceous materials and zeolites are non-reactive adsorbents that help to recover the Carbon dioxide from flue gases. Activated carbons and charcoals (high porous materials) exhibit CO2 capture capacities ranging from 10 to 15 % by weight. However, the CO2/N2 selectivity is relatively low. Carbon-based systems can be applicable when CO2 purity is not more than 90 % [26-27].

A. Chemical adsorption

Chemical adsorption is a subclass of adsorption which involves chemical reaction which occurs at the exposed surface. A wide range of metals have been studied including [28]

1) hydro talmates and double salts.
2) metal salts from alkali metal compounds: lithium silicate, lithium zirconate to alkaline earth metal compounds (i.e., magnesium oxide and calcium oxide),
3) metal oxides: CaO, MgO

In general, one mole of metal compound can react with one mole of CO2 with a reversible reaction. The process consists of a series of cycles where metal oxides (such as CaO) at 923K are transformed into metal carbonates form (such as CaCO3) at 1123K in a carbonation reactor to
regenerate the sorbent and produce a concentrated stream of CO2 suitable for storage [29-30].

Considerable attention was paid to calcium oxide (CaO) as it has a high CO2 adsorption capacity and high raw material availability (e.g., limestone) at a low cost. Lithium salts was recorded a good performance in CO2 adsorption, but it gained less focus due to its high production cost. Although double salts can be easily regenerated due to low energy requirement, their stability has not been investigated [31-32].

B. Physical adsorption

Activated carbon (AC) has a number of attractive characteristics like as its high Hydrophobicity, low cost, high adsorption capacity, and low energy requirement for regeneration [33-35]. Activated carbons are insensitive to moisture, inexpensive and easy for regeneration. These adsorbents have well developed micro and mesopore structures that are suitable for high CO2 adsorption capacity at ambient pressure [36-38].

V. Conclusion

In recent years, post-combustion capture has been the topic of many researches, because it is more flexible and can be easily added to the fossil fuel power plants. Based on above findings, it can be concluded that flue gases properties (mainly concentration of CO2, temperature and pressure) are the most effective factors for selection of suitable process for CO2 separation. Since flue gases have high temperature (about 373 K), low pressure, and low CO2 concentration (1 atm and 10–15% moL), bulk absorption and adsorption processes may be the best suitable process for CO2 separation from these streams. Due to simplicity of adsorption process, this process has been applied in industrial plants, although many researchers have been focused on preparation of adsorbents with high selectivity and capacity, in recent years. For industrial application, more studies about adsorbents are necessary. Cryogenic distillation and membrane processes are efficient for gas streams with high CO2 concentration. Therefore, these processes are economically efficient for pre-combustion capture. In recent years, different studies have been performed to optimize cryogenic cycles and preparation of suitable membrane for CO2 separation from post-combustion flue gases. By the result of this study, future research direction on the scale-up and industrialization of adsorption (with modified adsorbent), and membrane process for CO2 separation is suggested. Therefore more studies must be focused on modeling and simulation of these processes (membrane and adsorption), although research for finding new adsorbent, suitable membrane (with mixed or modified present membrane) and blending amine solvents can reduce CCS cost. We fabricated mixed matrix membranes demonstrating the ability to enhance the CO2 permeability of a neat polymer using an inexpensive silica gel filler particle. All the above discussion brings a review may be concluded that the mixed membrane method play an important role in the way to remove CO2 from flue gases.
